

How Well Does GDP per Capita Predict National Well-Being?

World Regions, Datasets, and Question Wording*

Abstract

Is GDP per capita a good predictor of national well-being? Using all waves of the World Values Survey and the European Values Study (WVS/EVS, 1981–2023, 112 countries), I find that log GDP per capita explains on average 14% of the cross-country variance of eight well-being indicators, and that a country’s broad world region is a better predictor, in and out of sample, in 85% of 1,008 specifications. This advantage stems from Latin America and the former Eastern Bloc, and it vanishes in the Gallup World Poll, where income predicts life evaluations as well as region. To understand why the two datasets disagree, I randomize the question wording (Cantril ladder vs. life satisfaction) and scale (0–10 vs. 1–10) in an online survey of 11,000 respondents in ten high-income countries. The ladder shifts answers by -0.45 points, with effects varying across countries, which explains why Gallup levels are lower than WVS levels. However, in the same ten countries, the two questions yield similar income gradients when asked to the same sample, whereas Gallup’s gradient is three times steeper than the WVS’s: the discrepancy stems from differences in samples, modes and context rather than wording.

*Data and code: https://github.com/bixiou/wellbeing_gdp_region [TODO: deposit data and code on a public repository (e.g. OSF) before acceptance; Gallup data cannot be redistributed]. The survey was approved by the CIRED institutional review board (IRB-CIRED-2025-2) and pre-registered at osf.io/7mzn4. I thank Claudia Senik and participants in the 2024 STATEC Well-being Conference for helpful comments, Armon Rezai and the Vienna University of Economics and Business (WU Wien) for access to the Gallup World Poll data, and Julieta Toffoli for research assistance. This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors. Declaration of interest: none.

Keywords: subjective well-being; life satisfaction; GDP; world regions; survey methodology; question wording.

JEL codes: I31; O15; O57; C83.

1 Introduction

Which country is the happiest? The answer most often heard, based on the World Happiness Report, is a Scandinavian, high-income country. Behind this answer lies one of the most robust stylized facts of well-being research: across countries, average life evaluations increase with the logarithm of GDP per capita (Deaton, 2008; Stevenson and Wolfers, 2008; Sacks et al., 2012). Using the Gallup World Poll, Deaton (2008) finds a correlation above 0.8 between average life evaluation and log GDP per capita; using the World Values Survey (WVS), Inglehart and Klingemann (2000) reported an R^2 of about one half for an index of happiness and satisfaction. These correlations are frequently invoked to support the view that economic growth is a reliable route to higher well-being.

This paper revisits the predictive capacity of GDP per capita for national well-being, and asks two questions. First, how much of the cross-country variation in well-being does GDP per capita actually predict, and does it predict it better than a very simple alternative, the country's world region? Second, why do the two main sources of cross-national well-being data, Gallup and the WVS, give different answers to the first question? Previous work has noted that income is more strongly related to Gallup's ladder than to WVS measures (Deaton, 2008), and that national income is more related to life evaluations than to happiness or emotions (Inglehart et al., 2008; Kahneman and Deaton, 2010). Yet whether the difference between datasets comes from the question asked or from the samples has, to my knowledge, not been tested experimentally.

For the first question, I use all seven waves of the WVS, complemented with the 2017 wave of the European Values Study (339 country-years), eight indicators of national well-being, and seven income measures, and I compare the variance explained by income and by region using the Shapley (LMG) decomposition of R^2 (Lindeman et al., 1980; Grömping, 2007) and leave-one-country-out cross-validation. For the second question, I embedded a 2×2 experiment in an online survey of 11,000 respondents in ten high-income countries, randomizing the wording (Gallup's Cantril ladder vs. the WVS life-satisfaction question) and the scale (0–10 vs. 1–10). Combining the experiment with Gallup and WVS data for the same countries, I decompose the Gallup–WVS gap into a question effect and a residual reflecting differences in samples, modes, context and time.

The results are threefold. First, in the WVS, GDP per capita is a weak predictor of

national well-being: it explains on average 14% of the variance of the eight indicators (20% with the best income measure), and nothing of the share of very happy people. Region is a better predictor in 85% of specifications and, out of sample, for every indicator. Second, this conclusion is fragile in two respects: it is driven by Latin America and the former Eastern Bloc, and it does not hold in Gallup, where income predicts life evaluations as well as or better than region: log GDP per capita explains 61% of the cross-country variance of Gallup’s mean ladder, against 48% for region. Third, the experiment shows that question wording has a sizeable effect on levels—the ladder shifts answers by -0.45 points, more than the average gap between Gallup and the WVS—and that this effect varies across countries. However, wording has little effect on the relationship between income and well-being, which is what the two datasets disagree about. Across the ten countries, the slope of mean life evaluation on log GDP per capita is 4.20 in Gallup but 1.36 in the WVS, whereas in the experiment it is 4.35 with the ladder and 4.05 with the satisfaction question. Likewise, within countries, richer respondents do not rate their lives relatively higher when asked the ladder question rather than the satisfaction question. The discrepancy between Gallup and the WVS is therefore attributable to differences between samples in the broad sense, not to the question asked.

The paper contributes to three literatures. It adds to the debate on the relationship between income and well-being across countries and over time (Easterlin, 1974; Easterlin et al., 2010; Stevenson and Wolfers, 2008; Deaton, 2008; Jebb et al., 2018) by showing that the strength of the cross-country relationship depends on the dataset, and by benchmarking income against regions. It relates to work on regional and cultural differences in well-being, in particular the high well-being of Latin America (Graham and Lora, 2009; Rojas, 2016) and the low well-being of transition countries (Guriev and Zhuravskaya, 2009), and on the comparability of well-being across cultures (Diener and Suh, 2000; Exton et al., 2015; Senik, 2014). Finally, it contributes to the methodological literature on the measurement of subjective well-being (Kahneman and Krueger, 2006; OECD, 2013; Stone and Mackie, 2013; Bond and Lang, 2019; Kaiser and Oswald, 2022), and specifically on the comparability of the Cantril ladder and life-satisfaction questions (Bjørnskov, 2010; Nilsson et al., 2024) and on context and mode effects (Deaton and Stone, 2016; Dolan and Kavetsos, 2016), by providing experimental estimates of wording and scale effects in ten countries.

Section 2 presents the data. Section 3 compares income and region as predictors of national well-being. Section 4 investigates the discrepancy between Gallup and the WVS. Section 5 discusses limitations, and Section 6 concludes.

2 Data

2.1 World Values Survey

The World Values Survey (WVS) is the longest-running cross-national survey of values and subjective well-being. I use the WVS time-series file (Haerpfer et al., 2022), which pools the seven waves conducted between 1981 and 2022, and complete it with the Joint EVS/WVS 2017–2022 dataset (EVS/WVS, 2024), which adds the 33 national surveys of the 2017 wave of the European Values Study (EVS, conducted in 2017–2021) and 2 recent WVS surveys (India 2023, Uzbekistan 2022). The EVS asks the same well-being questions, and the combination of the two surveys is standard practice (the so-called Integrated Values Surveys). When a country-year is present in both files, I keep the WVS time-series version. For brevity, I refer to the combined data as the WVS: 496,861 respondents in 339 country-years and 112 countries. National samples are designed to be representative of the adult population, typically with 1,000 to 3,000 respondents, and most interviews are conducted face-to-face (though some recent national surveys used web, mail or mixed modes, e.g. the WVS in the United States in 2017 and in Japan in 2019, or the EVS in Switzerland in 2017). All statistics use the survey weights provided by the WVS and the EVS.

The WVS contains two questions on subjective well-being:

- *Happiness*: “Taking all things together, would you say you are: *Very happy*; *Quite happy*; *Not very happy*; *Not at all happy*.”
- *Life satisfaction*: “All things considered, how satisfied are you with your life as a whole these days?”, answered on a scale from 1 (*Completely dissatisfied*) to 10 (*Completely satisfied*).

Non-responses are rare (1.4% for satisfaction and 1.7% for happiness on average) and uncorrelated with GDP per capita (correlation: -0.09); they are excluded.

Indicators of national well-being. Because there is no consensus on how to aggregate ordinal answers into a national indicator, and because the ranking of countries can depend on this choice (Bond and Lang, 2019), I compute eight indicators for each country-year:

- *Happy*: share answering *Quite* or *Very happy*;
- *Very Happy*: share answering *Very happy*;
- *Very Unhappy*: share answering *Not at all happy*;

- $V. \textit{Happy} - V. \textit{Unhappy}$: difference between the two previous shares;
- *Happiness (mean)*: mean happiness, with answers coded +3, +1, -1, -3;
- *Satisfaction (mean)*: mean life satisfaction;
- *Satisfied*: share answering 6 to 10 to the life-satisfaction question;
- *Happy + Satisfied*: average of *Happy* and *Satisfied*, the index used by Inglehart and Klingemann (2000).

For the life-satisfaction question, I also compute the shares answering 8–10, 9–10, 10, 1–4 and 1–2, which describe the tails of the distribution and are used for comparisons with Gallup. Finally, I compute the share of people whose satisfaction is below 60% of the national mean, by analogy with relative poverty lines. The indicators are positively but imperfectly correlated: across country-years, the correlation between *Happy* and *Satisfied* is 0.73, and between *Very Happy* and *Satisfaction (mean)* it is only 0.60.

2.2 Gallup World Poll and World Happiness Report

The Gallup World Poll interviews around 1,000 adults per country and year in more than 140 countries, by telephone where coverage is high (typically in high-income countries) and face-to-face elsewhere (Gallup, 2022). Its life-evaluation question is the Cantril ladder (Cantril, 1965): “Please imagine a ladder, with steps numbered from 0 at the bottom to 10 at the top. The top of the ladder represents the best possible life for you and the bottom of the ladder represents the worst possible life for you. On which step of the ladder would you say you personally feel you stand at this time?”

I use the distribution of answers by country and wave, tabulated from the Gallup World Poll microdata (2,351 country-years, 168 countries, 2006–2023), from which I compute the same satisfaction indicators as for the WVS: the mean and the shares answering 6–10, 8–10, 9–10, 10, 0–4 and 0–2. These distributions are unweighted. To cover the most recent years, I also use the ladder means published in the World Happiness Report 2026 (World Happiness Report, 2026), which average Gallup data over three years up to 2023–2025.

2.3 Income

My benchmark income measure is the log of GDP per capita at purchasing power parity (PPP, constant 2021 international dollars) from the World Development Indicators (World

Bank, 2026). As an alternative, I use GDP per capita at market exchange rates (constant 2015 US dollars). Missing values are filled in automatically, in three steps: (i) PPP series, which start in 1990, are extended backwards (and gaps filled) using the growth rate of real GDP per capita; (ii) for countries absent from the World Bank data (e.g. Taiwan, or Venezuela in recent years), I use the IMF World Economic Outlook (International Monetary Fund, 2026), whose values are in current dollars; I convert them into the constant dollars of the World Bank series by multiplying them by the ratio, in the same year, between the World Bank and the IMF values for the United States (a U.S. price deflator, since PPP and market-exchange-rate values coincide for the United States); (iii) remaining gaps are filled with the closest year available (Montenegro 1996). Territories without national accounts use the GDP of the closest entity (e.g. the United Kingdom for Northern Ireland). A robustness check excludes all imputed values.

Region is a categorical variable, which can capture non-linear patterns that a single continuous variable cannot. To compare income and region on an equal footing, I also use categorical income indicators: income sextiles and income clusters obtained by k -means clustering of log GDP per capita, with $k = 5, 6$ or 7 . The clusters let the data choose the thresholds between income groups and allow for non-linear relationships, at the cost of more parameters than the log-linear specification. Sextiles and clusters are recomputed in each estimation sample (e.g. each wave), so that they always partition the country-years being compared.

2.4 Regions

My main classification groups countries into the five UN regional groups (Figure 1): *Africa*, *Asia* (the Asia-Pacific group, which includes the Middle East and Central Asia), *Eastern Europe* (the former Eastern Bloc, excluding Central Asia), *Latin America* (including the Caribbean), and *Western* countries (the “Western European and Others” group: Western Europe, North America, Australia, New Zealand, and Turkey). It departs from the UN groups for two countries only: Israel, a member of the Western group since 2000 because it was denied access to the Asia-Pacific group, is classified in Asia, and Cyprus, a member of the Asia-Pacific group, is classified with Western countries. Territories that are not UN members (e.g. Taiwan, Hong Kong, Puerto Rico, Kosovo) are assigned to the group of their neighbors. For robustness, I use four alternative classifications: a six-region variant separating the Middle East and grouping Central Asia with the former Eastern Bloc; the seven World Bank regions; the five continents; and the UN geoscheme sub-regions (about twenty groups).

Figure 1: Main classification of countries into five world regions

2.5 A survey experiment on question wording and scale

Gallup and WVS differ in two respects that could explain why they disagree: the question (the Cantril ladder on a 0–10 scale vs. life satisfaction on a 1–10 scale) and everything else—sampling frames, interview modes, questionnaire context, translations, and survey years. To separate the two, I embedded a randomized experiment in an original survey (Fabre, 2025). The survey was conducted online between April 15 and July 3, 2025, by Bilendi (Kantar in Saudi Arabia) on 11,000 respondents in 10 high-income countries: the United States (3,000), Japan (2,000), Saudi Arabia (1,000), Germany (1,048), the United Kingdom (826), France (798), Italy (756), Spain (603), Poland (500) and Switzerland (469). (The survey also covered Russia, where the well-being question was not asked.) Samples were stratified with quotas on gender, age, income, education, region and urbanicity (race in the U.S.; citizenship in Saudi Arabia), and results are reweighted to match population frequencies along these dimensions (weights trimmed between 0.25 and 4). Respondents failing an attention test or completing the questionnaire in less than 6 minutes were excluded. The project was approved by the CIRED institutional review board (IRB-CIRED-2025-2) and pre-registered at the Open Science Framework (osf.io/7mzn4).

Toward the end of the questionnaire, after questions on global policies, each respondent was randomly assigned to one of four versions of the life-evaluation question:

- *Ladder 0–10* (Gallup’s original): the Cantril ladder question quoted in Section 2.2, with steps numbered from 0 (*Worst possible*) to 10 (*Best possible*);

- *Ladder 1–10*: same wording, with steps numbered from 1 to 10;
- *Satisfaction 0–10*: the WVS question quoted in Section 2.1, with answers from 0 (*Completely dissatisfied*) to 10 (*Completely satisfied*);
- *Satisfaction 1–10* (WVS’s original): same wording, with answers from 1 to 10.

This 2×2 design identifies the effect of wording (ladder vs. satisfaction) and scale (0–10 vs. 1–10), and their interaction, holding the sample, mode, context and time constant. Within each country, the four branches are balanced (each receives between 21% and 30% of respondents).

3 Income and region as predictors of national well-being

3.1 Empirical strategy

For each well-being indicator y and each income indicator x , I estimate three linear regressions across country-years i :

$$y_i = \alpha_1 + \beta_1 x_i + u_i \quad (1)$$

$$y_i = \alpha_2 + \gamma'_2 R_i + e_i \quad (2)$$

$$y_i = \alpha_3 + \beta_3 x_i + \gamma'_3 R_i + \varepsilon_i \quad (3)$$

where R_i is a vector of region dummies. Denoting R_1^2 , R_2^2 and R_3^2 their coefficients of determination, the share of the variance explained by income alone is R_1^2 . To compare income and region, I decompose R_3^2 between the two regressors following Lindeman et al. (1980) (LMG), i.e. using the Shapley value (Grömping, 2007). With two (groups of) regressors, the LMG contribution of income is the average of its contribution when entered first (R_1^2) and when entered second ($R_3^2 - R_2^2$). The *share of explained variance due to income* is therefore

$$s = \frac{R_1^2 + (R_3^2 - R_2^2)}{2 R_3^2}, \quad (4)$$

and region is the better predictor whenever $s < 50\%$.

Two features of this comparison could favor region. First, region has four degrees of freedom while log GDP has one. Second, the regions were not chosen blindly. To address the first concern, I report adjusted R^2 and, more directly relevant to the question of *predictive* capacity, leave-one-country-out cross-validated R^2 : each country’s observations are

predicted by a model estimated on all other countries, and the out-of-sample R^2 is one minus the ratio of the sum of squared prediction errors to the total sum of squares. To address the second concern, I report results for four alternative classifications. Other robustness checks include each WVS wave separately, excluding the EVS surveys, weighting countries by their population, keeping only the last observation of each country, excluding the pandemic years 2020–2021, excluding imputed GDP values, using the previous vintage of GDP data (PPP in constant 2017 dollars), and excluding Latin America and Eastern Europe.

3.2 Income explains a small share of national well-being in the WVS

Figure 2 plots mean life satisfaction against GDP per capita for all WVS country-years. The relationship is positive, but the dispersion at any given income level is large: countries with a GDP per capita around 10,000 dollars span most of the range of observed life satisfaction, from the former Soviet republics at the bottom to Latin American countries at the top. Log GDP per capita explains 23% of the variance of mean satisfaction.

Figure 2: Mean life satisfaction vs. GDP per capita (PPP), WVS/EVS 1981–2023

Note: Each point is a country-year (label: ISO code and last two digits of the year). The legend gives the R^2 of the regression on log GDP per capita.

Table 1 generalizes this result to all indicators and income measures. On average over

the eight indicators, log GDP per capita at PPP explains 14% of the variance, and the best-performing income measure (Cluster k=7 nominal) explains 20%. The indicators are positively but imperfectly correlated (Appendix Table A1), and satisfaction-based indicators are better explained than happiness-based ones: log GDP explains 5% of the variance of mean happiness and essentially none of the share of *Very happy* people, whose slope with respect to log GDP is statistically indistinguishable from zero (slope 0.003, $p = .915$; Appendix Table A2). This confirms the observation of Deaton (2008) and Inglehart et al. (2008) that income is more closely related to life evaluation than to happiness. By contrast, region alone explains 33% of the variance on average (last column).

Table 1: Share of the variance of national well-being explained by income alone (R^2), WVS/EVS 1981–2023

Well-being indicator	log GDP p.c.		Sextile PPP	Income cluster				Region
	PPP	nominal		k=5 PPP	k=6 PPP	k=7 PPP	k=7 nominal	
Happy	0.15	0.20	0.21	0.19	0.20	0.20	0.23	0.30
Very Happy	0.00	0.00	0.03	0.03	0.04	0.04	0.04	0.33
Very Unhappy	0.07	0.10	0.12	0.11	0.13	0.13	0.14	0.14
V. Happy – V. Unhappy	0.00	0.01	0.04	0.03	0.04	0.05	0.05	0.33
Happiness (mean)	0.05	0.08	0.10	0.08	0.09	0.10	0.11	0.33
Satisfaction (mean)	0.23	0.29	0.23	0.21	0.22	0.23	0.29	0.42
Satisfied	0.32	0.38	0.32	0.30	0.32	0.32	0.38	0.40
Happy + Satisfied	0.28	0.35	0.30	0.28	0.30	0.30	0.35	0.39
Mean	0.14	0.18	0.17	0.15	0.17	0.17	0.20	0.33
Max	0.32	0.38	0.32	0.30	0.32	0.32	0.38	0.42

Note: R^2 of the regression of each well-being indicator (rows) on each income indicator (columns), over 339 WVS/EVS country-years (a few with missing GDP are excluded). The last column gives the R^2 of the regression on region dummies.

3.3 Region predicts national well-being better than income in the WVS

Table 2 reports the share of explained variance due to income, s , for each indicator and income measure. It is below 50% in all cases: on average, the best income measure accounts for 33% of the variance explained jointly by income and region. The first split of a regression tree using log GDP and region as candidate variables is on region for 8 out of 8 indicators.

The result is not an artifact of the larger number of parameters of the region model. Out of sample, region predicts better than income for every indicator (Table 3): for mean satisfaction, the leave-one-country-out R^2 is 0.38 with region against 0.21 with log GDP. For several happiness indicators, income has no out-of-sample predictive power at all (negative cross-validated R^2).

Table 2: Share of explained variance due to income rather than region (LMG), WVS/EVS 1981–2023

Well-being indicator	log GDP p.c.		Sextile	Income cluster			
	PPP	nominal	PPP	k=5 PPP	k=6 PPP	k=7 PPP	k=7 nominal
Happy	0.29	0.36	0.38	0.35	0.37	0.38	0.41
Very Happy	0.00	0.01	0.07	0.06	0.08	0.10	0.10
Very Unhappy	0.28	0.37	0.43	0.40	0.47	0.47	0.50
V. Happy – V. Unhappy	0.01	0.02	0.09	0.07	0.09	0.11	0.11
Happiness (mean)	0.09	0.13	0.18	0.14	0.17	0.19	0.19
Satisfaction (mean)	0.32	0.38	0.31	0.29	0.31	0.32	0.38
Satisfied	0.43	0.49	0.43	0.40	0.43	0.43	0.49
Happy + Satisfied	0.39	0.46	0.42	0.39	0.41	0.42	0.46
Mean	0.23	0.28	0.29	0.26	0.29	0.30	0.33
Max	0.43	0.49	0.43	0.40	0.47	0.47	0.50

Note: Share of the R^2 of Equation (3) attributed to income by the LMG (Shapley) decomposition, Equation (4). Values below 0.5 indicate that region is the better predictor.

Table 3: Out-of-sample predictive capacity: leave-one-country-out cross-validated R^2

Data	Indicator	Obs.	log GDP PPP	Best income variable	Region	log GDP PPP + Region
WVS, all waves	Happy	337	0.12	0.18	0.26	0.32
WVS, all waves	Very Happy	337	−0.03	−0.04	0.27	0.26
WVS, all waves	Very Unhappy	337	0.06	0.10	0.10	0.11
WVS, all waves	V. Happy – V. Unhappy	337	−0.02	−0.03	0.27	0.26
WVS, all waves	Happiness (mean)	337	0.02	0.05	0.29	0.29
WVS, all waves	Satisfaction (mean)	337	0.21	0.23	0.38	0.46
WVS, all waves	Satisfied	337	0.30	0.34	0.36	0.50
WVS, all waves	Happy + Satisfied	335	0.26	0.31	0.35	0.47
WVS, last obs. per country	Happy	112	0.06	0.04	0.10	0.10
WVS, last obs. per country	Very Happy	112	0.01	−0.04	0.15	0.15
WVS, last obs. per country	Very Unhappy	112	0.04	0.06	0.00	0.02
WVS, last obs. per country	V. Happy – V. Unhappy	112	−0.01	−0.07	0.14	0.13
WVS, last obs. per country	Happiness (mean)	112	−0.04	−0.08	0.11	0.08
WVS, last obs. per country	Satisfaction (mean)	112	0.19	0.21	0.31	0.33
WVS, last obs. per country	Satisfied	112	0.30	0.32	0.32	0.39
WVS, last obs. per country	Happy + Satisfied	112	0.25	0.26	0.28	0.33
Gallup, all years (2006–23)	Satisfaction (mean)	2344	0.61	0.66	0.49	0.68
Gallup, all years (2006–23)	Satisfied	2344	0.65	0.72	0.52	0.72
Gallup, all years (2006–23)	Unsatisfied (0/1–4)	2344	0.63	0.65	0.48	0.68
Gallup, last obs. per country	Satisfaction (mean)	167	0.60	0.58	0.45	0.64
Gallup, last obs. per country	Satisfied	167	0.65	0.68	0.52	0.70
Gallup, last obs. per country	Unsatisfied (0/1–4)	167	0.65	0.60	0.48	0.67
WHR, 2023–25 average	Satisfaction (mean)	147	0.62	0.60	0.52	0.69

Note: Each country’s observations are predicted with a model estimated on all other countries. Cross-validated $R^2 = 1 - \sum(y - \hat{y}_{\text{out-of-sample}})^2 / \sum(y - \bar{y})^2$; it can be negative when a model predicts worse than the overall mean.

Table 4 summarizes 1,008 estimates (indicator $\times$ income measure $\times$ specification) using the WVS. Region is the better predictor in 85% of them (76% when restricting to the best income measure). The result holds in each wave except wave 4 (1999–2004, 40 countries), where income and region perform similarly; when countries are weighted by population; when keeping one observation per country; without the pandemic years; without imputed GDP values; with the previous vintage of GDP data; without the EVS surveys; and with the six-region or the UN sub-region classifications.

Table 4: Robustness: income vs. region across specifications and datasets

Specification	Obs.	Countries	R^2 income		R^2 region	Share of explained variance due to income		adj. R^2	Region better (share of cases)
			log PPP	best		log PPP	best

Note: Averages over well-being indicators (8 for the WVS; 7 satisfaction indicators for Gallup; mean ladder for the WHR). “Best” refers to the income measure with the highest average R^2 in the main WVS specification (Cluster $k=7$ nominal). “Region better” is the share of indicator $\times$ income-measure combinations for which $s < 0.5$.

3.4 Where the region advantage comes from

Three results qualify this conclusion. First, the advantage of region is driven by two well-known “anomalies”: Latin America, happier than its income would predict (Graham and Lora, 2009; Rojas, 2016), and the former Eastern Bloc, unhappier (Guriev and Zhuravskaya, 2009). Excluding these two regions, region is the better predictor in only 27% of cases. Second, the result depends on the granularity and design of the classification: with continents or World Bank regions, which do not isolate Latin America or the former Eastern Bloc, region is better in 48% and 55% of cases, respectively. Third, and most importantly, the conclusion does not carry over to Gallup data. In Gallup’s latest

observation for each of 168 countries, log GDP explains 61% of the variance of the mean ladder, against 48% for region, and income accounts for 60% of the explained variance (Appendix Table A3). Over all Gallup specifications, region is the better predictor in only 34% of cases, mostly for indicators of the upper tail of the distribution (shares answering 9–10 or 10), which are almost unrelated to income. With the latest WHR data (2023–2025), log GDP explains 63% of the variance of the ladder against 55% for region.

The relation between GDP and well-being is thus much weaker in the WVS than in Gallup. The same holds when restricting both datasets to the 184 country-years observed by both surveys: the R^2 of mean life evaluation on log GDP is 0.53 in Gallup and 0.16 in the WVS. Whether “GDP is a poor predictor of national well-being” therefore depends on which of the two datasets one trusts.

3.5 Other correlates and within-country evidence

What do regions capture? Appendix Table A4 decomposes the variance of mean satisfaction among income, region and one additional country-level variable from the WVS. The average perceived freedom of choice and control over one’s life (“how much freedom of choice and control you feel you have over the way your life turns out”) alone explains 63% of the variance of mean satisfaction; in a Shapley decomposition with income and region, it accounts for 42 percentage points, against 22 for region and 11 for income. This variable is itself a subjective evaluation, so this correlation should not be read causally, but it suggests that non-material dimensions of life are central to regional differences (Inglehart et al., 2008). Tolerance of homosexuality (24%), the importance of God (1%) and GDP growth over the previous five years (2%) explain much less.

Finally, the cross-sectional relation should not be confused with the relation over time. Within countries (country fixed effects, 309 observations from countries surveyed at least twice), mean satisfaction increases with log GDP per capita, with a slope of 2.28 per unit of $\log_{10}$ GDP (i.e. per tenfold increase), larger than the cross-sectional slope (1.14), and even the share of *Very happy* people increases (slope 0.20, $p < .001$). Income growth explains 0.34 of the within-country variance (Appendix Table A5). These within-country associations are consistent with Stevenson and Wolfers (2008) and Sacks et al. (2012) rather than with a strict version of the Easterlin paradox (Easterlin, 1974; Easterlin et al., 2010), although they may reflect common shocks (e.g. transition recessions) rather than the effect of income per se.

3.6 What are the happiest countries?

Rankings of countries depend on the indicator. Taking, for each indicator and each wave (and all waves combined), the happiest country-year, Switzerland appears most often (10 times out of 64), followed by Mexico (9) and Kyrgyzstan (6) (Appendix Table A6). The happiest country-years are Western (25), Latin American (19), Asian (15) or African (5). The richest countries are thus not necessarily the happiest: the link between income and well-being seems to be that rich countries rarely experience low well-being, rather than that they reach the highest levels.

4 Why do Gallup and the WVS disagree? Wording vs. samples

4.1 Experimental effects of wording and scale

Table 5 reports regressions of the answer on the randomized treatments, with country fixed effects, survey weights and heteroskedasticity-robust standard errors. The ladder wording shifts answers by -0.45 points on average (s.e. 0.05), i.e. respondents rate their lives lower on the “best possible life” ladder than when asked how satisfied they are. This is in line with evidence that the two questions elicit different considerations: in open-ended answers, the ladder evokes power and wealth more than life satisfaction does (Nils-son et al., 2024). The scale effect is smaller: answers on the 1–10 scale are 0.14 points higher than on the 0–10 scale (s.e. 0.05), which, once the 1–10 answers are linearly stretched to 0–10, amounts to -0.26 points. Wording and scale do not interact. Measured as the share of respondents answering 6 or more, the ladder changes the share “satisfied” by -9 percentage points.

Two further results matter for the interpretation of cross-country comparisons. First, the ladder does not steepen the income gradient *within* countries: the interaction between ladder wording and the income quartile is -0.004 ($p = .919$), against a gradient of 0.69 points per quartile (column 5). The scale does not change this conclusion: in a model interacting income with both wording and scale (column 6), the interaction between income and wording is 0.009 ($p = .883$) and the triple interaction is -0.023 ($p = .786$). So, at least among individuals in high-income countries, the ladder is not more “about money” than the satisfaction question. Second, the wording effect differs markedly across countries (Figure 3). It ranges from -1.12 points (Spain) to 0.36 (Japan), where the ladder yields *higher* answers than the satisfaction question, and the hypothesis of a common

Table 5: Effects of question wording and scale on life evaluation, Fabre (2025) survey experiment

Heteroskedasticity-robust standard-errors in parentheses

Signif. Codes: ***, 0.001, **, 0.01, *, 0.05

Note: OLS with country fixed effects, survey weights (normalized within country) and heteroskedasticity-robust standard errors in parentheses. *Ladder wording*: Cantril ladder (vs. WVS life satisfaction). *Scale 1–10*: answers from 1 to 10 (vs. 0 to 10). In columns 3 and 5, 1–10 answers are linearly rescaled to 0–10. Column 5 interacts the wording with the respondent’s income quartile within their country. * $p < .05$, ** $p < .01$, *** $p < .001$.

effect across countries is strongly rejected ($\chi^2(9) = 93.4$, $p < .001$). Question wording therefore affects not only the level but also the ranking of countries.

4.2 Decomposing the Gallup–WVS gap in ten countries

For each country c of the experiment, I define the observed gap between Gallup and the WVS as $D_c = G_c - W_c$, where W_c is the mean satisfaction in the latest WVS or EVS survey of the country (from 2017–2022, except for Saudi Arabia, 2003) and G_c the mean ladder in Gallup the same year (or the closest year, at most three years apart; 9 countries have an exact match). Comparing the two datasets in the same year removes the influence of changes in well-being over time. The experiment measures, within the same sample, the *question effect* $Q_c = F_c(\text{ladder } 0\text{--}10) - F_c(\text{satisfaction } 1\text{--}10)$, where $F_c(v)$ is the mean answer to variant v in country c . The residual $R_c = D_c - Q_c$ is the part of the gap due to everything that differs between the two datasets except the question: sampling frames, interview modes, questionnaire context, translations, and survey-specific time effects. This decomposition assumes that the question effect measured online in 2025 applies to the Gallup and WVS samples of earlier years.

Table 6 and Figure 4 present the decomposition for each country, and Table 7 sum-

Figure 3: Mean answer by question variant and country, Fabre (2025)

Note: Weighted mean answer on the native scale of each variant (0–10 or 1–10).

marizes it with 95% confidence intervals from a bootstrap that resamples respondents in the three surveys. On average, the gap between Gallup and WVS answers is $D = -0.60$ points. The question effect is even larger in absolute value: $Q = -0.71$ points. Wording (and scale) thus fully account for the fact that Gallup yields lower levels than the WVS in high-income countries, and the residual is small and not significantly different from zero ($R = 0.11$, 95% CI $[-0.04; 0.26]$). Since the two components move in opposite directions, another way to summarize the level difference is to compare the size of the two movements: the question accounts for $|\bar{Q}| / (|\bar{Q}| + |\bar{R}|) = 0.86$ (95% CI $[0.76; 0.99]$) of the gross difference in levels between Gallup and the WVS, and for 0.69 on average when this share is computed country by country. By this metric, wording is the main driver of the difference in *levels*.

What matters for correlations with GDP and for country rankings, however, is not the level of the gap but its variation across countries, which the previous metrics do not capture: a question effect that shifted all countries by the same amount would score high on them while leaving correlations and rankings unchanged. Here, the question effect explains little: the share of the cross-country variance of the gap attributable to the question, $\text{cov}(D, Q) / \text{var}(D)$, is 0.11 (95% CI $[-0.33; 0.55]$), and the residual accounts for the rest. Predicting a country's Gallup score by adding its experimentally measured question ef-

Table 6: Decomposition of the Gallup–WVS gap by country

Country	Year WVS/EVS (Gallup)	Survey: mode	Gallup (1)	WVS/EVS (2)	Gap D (1)–(2)	Ladder 0–10 Fabre (2025)	Satisf. 1–10	Question effect Q	Residual R $D - Q$

Note: Mean answers on native scales (Gallup: 0–10; WVS/EVS: 1–10). The Gallup year is given in parentheses when it differs from the WVS year. Survey: mode: source of the WVS/EVS data and main interview mode(s) (CAPI: computer-assisted personal interviews).

Figure 4: Observed Gallup–WVS gap, question effect and residual by country

fect to its WVS score does worse (root mean squared error: 0.54) than simply adding the average gap (0.35). The conclusion is the same when excluding Saudi Arabia, the only country whose latest WVS survey is not recent (variance share: 0.16), and for the share of respondents answering 6 or more (0.04). For instance, Japan is the only country with a positive question effect, but the gap is negative there; and in the United States, the gap is nil although the question effect is as large as in other countries.

Table 7: Decomposition of the Gallup–WVS gap: summary

Statistic	Estimate [95% bootstrap CI]
Mean gap D (Gallup – WVS)	–0.60 [–0.64; –0.55]
Mean question effect Q (wording + scale)	–0.71 [–0.84; –0.56]
Mean residual R (sampling, mode, context)	0.11 [–0.04; 0.26]
Share of mean gap due to question ($\bar{Q}/\bar{D}$)	1.19 [0.94; 1.45]
Share of gross level difference due to question ($ \bar{Q} /(\bar{Q} + \bar{R})$)	0.86 [0.76; 0.99]
Same, country average ($ Q_c /(Q_c + R_c)$)	0.69 [0.56; 0.72]
Share of cross-country variance of D due to Q ($\text{cov}(D, Q)/\text{var}(D)$)	0.11 [–0.33; 0.55]
Share of cross-country variance of D due to R	0.89 [0.45; 1.33]
Mean absolute gap $ D $	0.60 [0.56; 0.65]
Mean absolute residual $ R $	0.43 [0.33; 0.60]
Correlation between D and Q	0.09 [–0.26; 0.41]
Mean gap, share satisfied (6+)	–0.07 [–0.08; –0.06]
Mean question effect, share satisfied (6+)	–0.11 [–0.14; –0.08]
Variance share due to Q , share satisfied	0.04 [–0.33; 0.45]

Note: 10 countries. 95% confidence intervals from 1,000 bootstrap replications resampling respondents within country $\times$ variant (Fabre), within country (WVS), and answers within country (Gallup, multinomial).

Two direct comparisons of samples asked the same question corroborate the importance of the residual. First, Gallup respondents (World Happiness Report, 2023–2025) rate their lives 0.75 points higher on the 0–10 ladder than Fabre (2025) online respondents asked the same question, with differences ranging from 0.16 to 1.24 across countries. Second, WVS respondents report 0.75 points higher satisfaction than online respondents asked the WVS question (this comparison also includes changes over time, as WVS surveys are older). These sample (and mode) effects are of the same order of magnitude as the question effect, and they vary across countries. Even in the United States, where the 2017 WVS was itself conducted online, WVS respondents report 0.49 points higher satisfaction than Fabre (2025) respondents.

4.3 Income gradients in the ten countries: past vs. new data

The decomposition above concerns levels. The question that motivates this paper, however, is whether the two datasets disagree on the *relationship* between income and well-being because of their questions. The ten countries of the experiment provide a direct test (Table 8). In the past data, the income gradient is much steeper in Gallup than in the WVS: across the ten countries, the slope of mean life evaluation on $\log_{10}$ GDP per capita is 4.20 in Gallup and 1.36 in the WVS, a difference of 2.84 (95% bootstrap CI [2.37; 3.26]), and log GDP explains 0.75 of the cross-country variance in Gallup against 0.16 in the WVS. In the new data, where the same sample answers either question, the gradient is similar with both wordings: 4.35 with the ladder and 4.05 with the satisfaction question, a difference of 0.30 (95% CI [−1.21; 1.96]); the two other variants yield intermediate slopes. Both original questions thus yield a gradient close to Gallup’s. The effect of wording on the gradient is imprecisely estimated, but it is significantly smaller than the difference between Gallup and the WVS: the part of this difference that is not due to the question is 2.54 (95% CI [0.90; 4.18]). The flat gradient of the WVS is thus mostly specific to its samples, not to its question. This is consistent with the individual-level evidence that the ladder does not steepen the income gradient within countries (Section 4.1). Two caveats apply. First, the bootstrap confidence intervals reflect the sampling of respondents and treat the ten countries as given; with ten countries, the slopes themselves are imprecise (Table 8 reports their standard errors across countries). Second, the R^2 differ more than the slopes, because the satisfaction question produces more dispersion around the income gradient (notably in Japan), and the decompositions between income and region are uninformative here, since Poland is the only Eastern European country.

Table 8: Income gradient of national well-being in the ten countries of the experiment: past vs. new data

Data	Slope on $\log_{10}$ GDP	s.e.	R^2 income	R^2 region	Share due to income
Gallup (ladder 0–10)	4.20	0.80	0.75	0.29	0.78
WVS/EVS (satisfaction 1–10)	1.36	1.44	0.16	0.34	0.35
Fabre 2025: ladder 0–10	4.35	1.05	0.76	0.14	0.91
Fabre 2025: ladder 1–10	2.57	1.36	0.33	0.50	0.36
Fabre 2025: satisfaction 0–10	3.21	2.03	0.23	0.36	0.35
Fabre 2025: satisfaction 1–10	4.05	2.09	0.31	0.29	0.52

Note: OLS across the 10 countries of the experiment. Gallup and WVS/EVS: latest WVS/EVS survey and Gallup the same year, GDP of that year. Fabre (2025): mean answer by variant, GDP of 2025. Standard errors robust to heteroskedasticity (HC1). R^2 income, R^2 region and share due to income: see Section 3.1 (regions: Western, Asia, Eastern Europe).

Two further comparisons of samples asked the same question confirm that sample

differences are large. First, the EVS and the WVS surveyed 7 countries separately during 2017–2022, with the same satisfaction question; their mean satisfaction differs by 0.31 points on average (up to 0.53), a magnitude comparable to the cross-country variation of the Gallup–WVS gap. Second, as noted above, Gallup and WVS respondents report markedly higher well-being than online respondents asked the same question.

4.4 The global discrepancy

The ten countries of the experiment are all high-income, whereas the Gallup–WVS discrepancy matters most for the global relation between GDP and well-being. Restricting both datasets to the 184 country-years (99 countries) observed by both surveys the same year, log GDP explains 0.53 of the variance of Gallup’s mean ladder but only 0.16 of WVS mean satisfaction, and income accounts for 51% of the variance explained jointly with region in Gallup against 24% in the WVS. The gap between the two datasets increases strongly with GDP (Figure 5): the slope is 1.09 per unit of $\log_{10}$ GDP (s.e. 0.14, clustered by country), with WVS answers exceeding Gallup answers by around two points in low-income countries, against less than half a point in high-income countries.

Figure 5: Gallup ladder minus WVS satisfaction in the same country-year, by GDP per capita

Note: Mean answers on native scales (Gallup: 0–10; WVS: 1–10), 184 country-years observed by both surveys. Line: OLS fit with 95% confidence band.

Could the question explain this pattern? Within the experiment, the question effect is

not significantly related to GDP (slope 0.30, s.e. 1.75), which is unsurprising given the narrow range of GDP among the ten countries. Even taking this point estimate at face value and extrapolating it to all countries, adjusting WVS answers for the predicted question effect would raise the R^2 of WVS satisfaction on log GDP only from 0.16 to 0.26, far from Gallup’s 0.53. The experiment cannot rule out that the wording effect is much larger in low-income countries—for instance if the “best possible life” evokes material comparisons more strongly where material deprivation is widespread—but nothing in the high-income evidence points in that direction: the ladder does not steepen the individual income gradient (Section 4.1), and the country-level question effects are unrelated to the observed gaps.

5 Discussion

5.1 Income vs. region

Several caveats apply to the comparison between income and region. First, region is not a mechanism: it bundles culture, history, institutions, social ties, and possibly cross-cultural differences in how people use response scales (Chen et al., 1995; Diener et al., 2003; Exton et al., 2015). If regional differences partly reflect response styles, then region predicts *measured* well-being without necessarily predicting *experienced* well-being. Existing evidence suggests that self-reported well-being carries information about true well-being (Sandvik et al., 1993; Kaiser and Oswald, 2022), and studies exploiting migrants suggest that national differences partly reflect a cultural component of well-being rather than mere translation artifacts (Senik, 2014; Exton et al., 2015), but the present analysis cannot separate these interpretations. Anchoring vignettes (Kapteyn et al., 2010) or measures of emotional well-being would help.

Second, the advantage of region rests largely on Latin America and the former Eastern Bloc. These are well-documented deviations from the income gradient, but they are not independent of the classification: grouping countries into continents or World Bank regions, which do not isolate these groups, weakens the result. The fairest summary is that GDP per capita leaves much of the cross-country variation unexplained, and that a few large regional deviations explain more of it than income does in the WVS.

Third, the analysis pools country-years that are not independent, and R^2 decompositions carry no information on causality. The within-country evidence shows that growth is associated with rising life satisfaction, so the weak cross-sectional relation does not imply that income is irrelevant for well-being.

Fourth, and most importantly, the WVS and Gallup disagree on the strength of the income gradient. In Gallup, income predicts life evaluations about as well as region, or better.

Section 4 showed that this discrepancy comes mostly from differences between samples in the broad sense, not from the question asked: asked to the same sample, the ladder and the satisfaction question yield similar income gradients.

5.2 Wording vs. samples

The experiment shows that the question matters for levels: the Cantril ladder yields lower answers than the WVS life-satisfaction question, and this difference fully accounts for the lower average level of Gallup data in high-income countries. But the question does not explain the cross-country pattern of the Gallup–WVS gap, which is what drives differences in correlations with GDP and in country rankings: asked to the same sample, both questions yield similar income gradients, close to Gallup’s. The pattern is explained by the residual, i.e. by differences between samples in the broad sense: sampling frames, interview modes (Dolan and Kavetsos, 2016; Conti and Pudney, 2011), questionnaire context (Deaton, 2012; Deaton and Stone, 2016), translations, and time.

Several limitations should be kept in mind. First, the experiment covers ten high-income countries, whereas the gap varies most across income levels. The question effect could be different in low- and middle-income countries, where both Gallup and the WVS mostly interview face-to-face; only an experiment in these countries can settle this. Second, the residual lumps together several factors that the design cannot separate. In particular, the question effect was measured with the survey’s own translations, toward the end of a questionnaire on global policies, and online; it may differ from the effect that would be obtained with official Gallup and WVS translations, at the beginning of an interview, and face-to-face or by phone. Third, the decomposition assumes that the question effect measured in 2025 applies to the WVS/EVS and Gallup surveys of 2017–2022 (2003 for Saudi Arabia). Fourth, with ten countries, cross-country statistics are imprecise, as shown by the bootstrap confidence intervals. Finally, online panel respondents report markedly lower well-being than Gallup and WVS respondents asked the same question, a sample and mode effect that deserves attention in its own right as online panels become common in well-being research.

6 Conclusion

GDP per capita is a weaker predictor of national well-being than is often assumed, but how weak depends on the data. In the WVS, it explains a small share of the cross-country variance of well-being, less than a country's world region, and it explains essentially nothing of the share of very happy people. In the Gallup World Poll, however, income predicts life evaluations as well as region does. A survey experiment in ten high-income countries shows that the question matters for levels—the Cantril ladder yields lower answers than the life-satisfaction question—but that it has little effect on the relationship between income and well-being: asked to the same sample, both questions yield an income gradient close to Gallup's, whereas the WVS gradient is much flatter. The discrepancy between the two datasets therefore reflects differences in samples, modes, and context.

These findings have two implications. For research, cross-country conclusions about the income–well-being relationship should be checked across datasets, and the choice between Gallup and the WVS should be based on the quality and comparability of their samples rather than on their questions, since wording effects mostly shift levels. Gallup's standardized annual methodology is an argument in its favor for cross-country comparisons, and in the ten high-income countries studied, an independent online sample reproduces Gallup's income gradient rather than the WVS's. However, the gap between datasets is largest in low-income countries, where neither the present experiment nor existing evidence can yet tell which survey is closer to the truth. Replicating the experiment face-to-face in low- and middle-income countries is the natural next step. For policy, the fact that rich countries rarely have low well-being, while many countries at intermediate income levels are as happy as the richest, suggests that growth is neither necessary nor sufficient for high well-being, and that the non-material determinants of well-being that differ across regions deserve more attention in policy evaluation (Stiglitz et al., 2009; Frijters et al., 2020).
